# Small Scale Renewables

# **Practical Guide**

There are many opportunities for small scale renewables to provide a source of heat or power for the farm.

Using renewables reduces the demand for energy obtained by burning fossil fuels. This results in less harmful greenhouse gas (GHG) emissions, savings on fuel bills and may help to reduce the farm's carbon footprint.

The profitability and payback of suitably designed schemes relies on making the best use of the onsite generation and offsetting reliance on grid bought energy. This can see a good return on investment, especially at times of market volatility and increasing energy bills. Schemes such as Smart Export Guarantee (SEG) ensures that you are paid for any excess electricity that cant be used on site being sent to the grid.

Small scale renewables are worth considering, especially if you are planning any renovations, building a new house or converting a steading. New developments should consider orientation in relation to solar gain and cooling, natural day-lighting and ventilation, plus the energy efficiency of the construction materials to make the most of energy use. Always look at options to reduce energy demand and improve energy efficiency before installing any renewable technology.

Renewable technologies can be useful for remote properties where the farm is 'off-grid' and unable to connect to mains electricity or gas. Onfarm renewables can also form part of a wider group investment or community scheme.

### Top tips for every farm:

- ✓ Assess current energy use. An energy audit will identify losses and assess energy and heat needs.
- ✓ Consider renewables when planning a new building or a conversion it's usually easier to install at the start rather than retrofit.
- ✓ Small scale renewables may be useful for off-grid situations.
- ✓ Most schemes, especially wind, hydro and solar would require back up from another source of energy.
- ✓ Using an MCS (Micro-generation Certification Scheme) certified installer ensures that equipment meets good standards of performance and that installers adhere to safety standards.

This Practical Guide gives an overview of small farm scale renewable systems

# Our Practical Guides cover five useful topics:

- 1. Use energy and fuels efficiently
- 2. Renewable energy
- 3. Lock carbon into soils and vegetation
- 4. Making the best use of nutrients
- 5. Optimise livestock management

# **Small Scale Renewables**

## Solar water heating

Solar water heating uses the energy from the sun to warm a liquid in special panels or tubes called solar collectors. Solar panels are typically mounted on un-shaded, south facing roofs.

Technological improvements over recent years have increased efficiency and reliability. There are currently two main systems on the market – flat plate and evacuated tube.

Flat plate collectors are basically an insulated box with a black metallic sheet on the back with pipes in front with liquid, which is heated and circulated to a connected overhead water tank by convection.

Evacuated tube systems comprise of a series of tubes which contain fluid inside an absorber tube which is in a vacuum. Heat cannot easily travel through the vacuum so the tubes transfer heat from the collector to a storage tank via a manifold. Evacuated tube systems are more efficient than flat plate systems but are more expensive.

Typical supplementary systems can cost from £3,000 upwards. A correctly sized unit may provide 100% of your hot water during the summer months. However, over a whole year the solar collectors will only meet approximately one third of demand, therefore an additional system to provide additional water heating will likely be required.

Planning legislation usually classes these installations as a permitted development and planning permission may not be required. However, exceptions do exist, for example if you are in a conservation area, and guidance from the local planning authority should always be sought.

## Micro hydro schemes

Hydro-power systems convert potential energy stored in water within a stream, river or pond to kinetic energy used to turn a turbine and produce electricity.

Key factors affecting viability are the height over which the water falls (the head), the catchment area of the waterbody, the distance of the stretch of water and the flow rate of the water course.

The term 'micro' usually applies to schemes producing less than 100 kW - many of the schemes considered at a farm scale are in this category.

In remote areas where an-off grid system is to be implemented, power can be supplied directly or via a battery bank and inverter. A back-up power system may be required to compensate for seasonal variations in water flow.

Hydro schemes must be designed and sized accurately to ensure maximum efficiency. Some systems could be up to 90% efficient, although a more realistic figure for small scale installations is perhaps around 50%.

Micro-hydro scheme costs are very site specific and are not always related to energy output. For a low head system, which uses for example, an existing pond, the costs may be in the region of £4,000 per kW installed.

For installations with medium head costs are typically £25-30,000 for a 5 kW unit.

The source should be situated close to where the power is to be used or near to a suitable grid connection.

The environmental impact of micro-hydro schemes is also of prime importance; environmental concerns include fish migration and keeping a minimum volume of water in the water body all year round.

It would be worth discussing your plans with both SEPA and the local planning authority before any work commences. See specific SEPA guidance at:

www.sepa.org.uk/regulations/water/hydropower/

#### **Potential risks**

Renewable energy systems are unlikely to be able to provide power 100% of the time. Fluctuations in wind speed, reduced water volume for micro-hydro or low sunlight levels for solar could affect output; additional space and water heating systems may be required to supplement supply.

Profitable schemes need to be appropriately scaled and designed to meet onsite demand, offset bills and take advantage of any revenue generation options.

Distance to and the availability of grid connection may be an issue, especially for larger schemes.

Check what is required in terms of planning and environmental considerations. Different technologies will have different requirements.

#### A kilo what?

**kW** - kilowatt. A unit of power equivalent to 1000 watts.

**kWh** - kilowatt hour. Measure of energy. For example a 100 watt light bulb will use 1kWh electricity over 10 hours.

**kWp** - kilowatt peak. Peak or maximum power output of a device under standard test conditions. Often used to compare solar devices.

**kWe** - kilowatt electric. The Electrical power output of device (used with CHP systems, which will also have a heat output, kWth).

# **Small Scale Renewables**

## **Heat pumps**

Heat pumps are basically refrigerators running in reverse and are becoming more common in domestic situations, especially with the phasing out of gas boilers in new build properties. They collect low temperature heat from a large area and provide higher temperature heat over a small area. Systems range from Water to Water, Air to Water, Air to Air, etc. with the most popular being a Water to Water system.

Heat from sunlight helps to maintain a constant soil temperature at a 1m depth of between 7°C and 13°C. A ground source heat pump (GSHP) can transfer this heat to a building, contributing towards space heating and hot water requirements. For a GSHP, a system of pipe-work is laid at a depth of approximately 1.5 m. The pipes contain a liquid which absorbs the stored heat within the ground and transfers it, via a heat pump, to hot water storage tanks. These tanks then supply the building heating system and hot water cylinder. GSHP do require electricity to run, but for every 1 kWh of energy supplied in a well designed system, provides up to 4 kWh of usable heat in return.

Borehole-type systems are available for smaller sites. These tend to be a more expensive option, however, can also be more efficient.

Although water temperatures produced from a GSHP are less than a typical oil or gas boiler, GSHP systems are ideal for new build or conversion work using under-floor heating, because the mass of the concrete floor slab can act as an effective radiator.

Although costs will be site specific, installation of a typical 8 kW system, suitable for an average house, could be in the region of £8,000 - £10,000 plus additional heating and radiator systems.

An alternative to Water to Water GSHP is the installation of an Air to Water Heat Pump (ASHP), which can extract the heat from ambient air temperature to warm water with a feed to a buffer tank and under-floor heating as described above. These systems are less expensive to install, ideal for smaller sites and overall are only slightly less effective. However, their seasonal efficiency is not as good because they work less well when the outside air temperature is low.

Air to Air systems are becoming more popular, especially for smaller dwellings up to a maximum floor area of 150m<sup>2</sup>. An additional heat source may be required during the colder months.

ASHP units work in the same way as an air conditioning unit but in reverse, feeding warm air into the premises. The installation cost could be as little as £2,500 dependent on number of units and output required.

### Key Facts...

- The cost of renewable energy systems vary. A wood burning stove with a 5 kW rating could cost around £1,000; a 5 kW wind turbine could be in excess of £25,000
- CARES support may be available. Rural businesses and communities can apply for loans and grants to help fund various aspects of projects. Eligibility of funding is very project specific and more info can be found on the Local Energy Scotland website.
- Funding support may be available through Business Energy Scotland and Home Energy Scotland. Banks and financial institutions can also offer favourable rates on loans for green and renewable projects.
- Most renewables could be expected to have a 20 year lifespan - however, a microhydro scheme could run for 50 years plus, with routine maintenance
- Suitability for renewables will depend on the site and identifying the right technology
- Renewable energy means less fossil fuel based energy sources are required. This could lower the fuel bill and the carbon footprint.

### **Small scale wind turbines**

Small scale wind turbines are one of the most popular and common options for farmers and rural households. If considering a wind turbine, you will first need to think about possible sites. Monitoring to establish actual wind speeds at selected sites will indicate feasibility, potential yield and will help you to select the most suitable location and type of turbine for your requirements on the farm.

Typical small scale installations range from 5 kW to 50 kW installed capacity with possibly the most common of the smaller turbines being a 15 kW unit with a hub height of approximately 15 m off the ground and rotor blade diameter of approximately 8.0 m. This will usually have a total generation meter with a connection to the local electricity network, allowing any unused electricity to be sold back to a power company. Typical installation cost for this system is approximately £40,000.

Siting in relation to neighbouring dwellings, proximity to grid connection, existing tree belts and prevailing wind direction are all important considerations. Planning permission will be required though can be less onerous for smaller turbines than for larger scale wind turbines. See <u>Farming</u> for a Better Climate Practical Guide on wind energy for more details.

# **Small Scale Renewables**

#### Payback mechanisms

Small scale renewables in the past were able to benefit from RHI and FIT payments. As the renewable technologies became more established, these schemes have closed to new applicants.

Many small scale renewables no longer need to rely on incentive payments to be financially viable as the lower cost of the technology and the savings from offsetting energy bills can make small scale renewable projects an economically viable option.

Make the best use of onsite generation and match the technology to your onsite demand. This will offset grid bought power and reduce reliance on fossil fuel derived energy, helping to save you money, especially at times of escalating energy prices.

Any excess generation that is not used on site may be sold to the grid and payments received through export tariffs (SEG) or power purchase agreements (depending on the scale and setup) can provide alternative forms of revenue. However, using the majority on site to offset your bills is often the motivating factor and most economic option.

#### Anaerobic Digestion (AD)

AD produces energy from a 'feedstock', as bacteria breakdown organic matter in a controlled environment to produce biogas. Suitable feedstocks include slurry and manures, maize or grass silage or other green or food waste from sources off the farm. Most AD plants are large scale but some smaller options do exist. AD plants can be costly to set up and do need daily management, but in the right circumstance could provide a useful opportunity for generating gas for heating, hot water or electricity production.

### **Biomass**

There are various biomass systems available on the market. These include domestic log burning stoves and stoves with back-boilers, which can heat water, to much larger pellet or woodchip burners that can provide space and water heating for larger domestic and farm buildings.

Biomass systems are currently deemed to be a low carbon technology as they return the same amount of  $CO_2$  to the atmosphere as the trees locked up while they were growing (though, this will depend on other variables such as harvest method and transportation to site). It is important that the biomass you are using is sustainably sourced (if you are still receiving RHI payments then you need to comply with sustainability criteria).

There are a number of things you will need to consider if looking at biomass heating. The boiler needs to be correctly sized for the heat requirement. Wood pellet and wood chip burners are similar in price, however fuel cost and availability

may differ depending on your location. Some chip boilers can also burn pellets.

Delivery and storage of chip or pellets also needs consideration. Are there regular, local deliveries in your area? Pellets are available in bags as small as 25 kg. Woodchips requires more volume for bulk storage though may be more readily available than pellets and are cheaper.

### **Solar Photovoltaics**

Solar photovoltaic (PV) systems produce electricity directly from daylight. PV can be located on independent structures adjacent to property, retrofitted to existing roofs, incorporated into the roof design as tiles in the external layer or mounted at ground level forming a bank of solar arrays for larger schemes.

PV panels should be sited in a south facing direction; the best system is a PV array connected to the national grid with an inverter to change power from DC (direct current) to AC (alternating current). This will also allow two-way metering, allowing power to be sold off to the grid when a surplus of energy has been generated, or bought in when demand exceeds the current level of generation.

The price of PV panels has fallen considerably as the technology became more established and the efficiency and life expectancy of panels has also improved.

A typical installation cost for a domestic roof-mounted installation rated at 2.5kWp could be in the region of approximately £3,500 and could pay for itself within 10 years depending on onsite use and current electricity prices.

In remote areas where a grid connection is not feasible, the use of PV cells plus batteries for energy storage may be considered as an option for providing light and power to dwellings and farm buildings. A mixture of renewable technologies often proves beneficial in these circumstances.

Roof mounted solar panels are usually classed as a permitted development, however, guidance from the local planning office should always be sought at an early stage as exceptions do exist.
